African Americans (AAs) have worse COVID-19-related outcomes than Caucasians and Asians, a disparity currently attributed to potential social and economic factors. In this commentary, we endeavor to examine important race-related differences in intrinsic thrombogenicity as another significant contributing factor and propose objective hemostasis assessments to address racial disparities in COVID-19 outcomes.

A prothrombotic state plays a central role in the prognosis of patients with COVID-19 with increased venous and arterial clotting commonly described. Severe COVID-19 is associated with high D-dimer, fibrinogen, and von Willebrand factor levels, and various levels have been reported to predict dosing strategies, mortality, and potential benefit from anticoagulation. A D-dimer >2600 ng/mL predicted venous thromboembolism (VTE) (area under the curve 0.760, 95% CI, 0.661–0.858; p 0.0001, sensitivity 89.7%, and specificity 59.5%) among American ICU patients [1]. Also, elevated acute phase reactants (C-reactive protein, fibrinogen, ferritin), and proinflammatory cytokines (tumor necrosis factor- α and interleukins-1 and -6) are COVID-19 hallmarks.

Racial disparities in thrombotic risk have been widely described in the pre-COVID-19 era. AAs have higher VTE rates than Caucasians, whereas Caucasians have higher rates than Asians/Pacific Islanders [2]. African Americans with coronary artery disease (CAD) have poorer cardiovascular outcomes, particularly death, than Caucasians and Asians. The highest ischemic event rate after elective

percutaneous coronary intervention (PCI) was reported in AA women. This group also had the highest platelet-fibrin clot strength as measured by thromboelastography, a marker independently predictive of ischemic events [3]. AA women had higher thrombin-induced platelet-fibrin clot strength than Caucasians and race was an independent predictor of high thrombin-induced platelet-fibrin clot strength by multivariate analysis in another CAD study [4]. Thromboelastography in age- and sex-matched East Asians and Caucasians (n=249 each) with stable CAD demonstrated delayed initiation of clot formation, lower clot strength, and greater clot lysis in the former race [5]. The disconnect between heightened platelet reactivity and lower post-PCI ischemic event rates, particularly stent thrombosis, and higher bleeding in East Asians (a phenomenon called the "East Asian Paradox"), further supports greater endogenous antithrombosis in East Asians [5].

Thrombotic outcome disparities have been attributed to specific hemostasis factors

(Table 1). Caucasians more often have prothrombotic factor V and prothrombin genetic mutations than Asians. AAs have the highest factor VIII, plasmin-antiplasmin complex, and von Willebrand factor levels versus intermediate levels in Caucasians and Hispanics and the lowest levels in Asians (Table 1). D-dimer is highest in AAs and lowest in Asians. Additionally, endothelial dysfunction is observed more often in AAs than Caucasians, and disparate regulation of the Gq pathway after protease-activated receptor-4 (PAR-4) stimulation associated with greater platelet activation has been reported (Table 1).

Caucasians also have higher CRP than Asians. After adjusting for age, socioeconomic status, BMI, and other risk factors, AA race was associated with increased CRP, and fibrinogen was higher in AAs than Caucasians despite demographic adjustments (Table 1). The totality of evidence supports that AAs have the most elevated inflammation and thrombosis biomarkers, followed by Caucasians (especially of European descent) and then Asians. The prothrombotic stimulus induced by COVID-19 combined with inherent greater thrombogenicity likely contributes to the disparity in clinical outcomes among

Table 1
Race -related differences in intrinsic thrombogenicity and inflammation.

Factors	Race/Ethnicity effect	Interpretation
Factor V Leiden and G20210A mutation ^{a,b}	Caucasians > Asians	Prothrombotic
Fibrinogen, factor VII, factor VIII, Plasmin-antiplasmin complex and VWF levels ^{c,d}	African Americans > Caucasians > Asians	Prothrombotic
D-dimer levels ^{d,e}	African Americans > Caucasians > Asians	Prothrombotic
Efficient coagulation inactivation by APC or enhanced fibrinolysis ^f	Asians > Caucasians	Fibrinolytic
Longer occlusion time on Global Thrombosis Test ^g	Japanese > Westerners	Delayed clot initiation
Prolonged time of initiation of clot formation; lower level of clot strength; increased activity of clot lysis ^h	East Asians > Caucasians	Delayed clot initiation; Fibrinolytic
High on treatment platelet reactivity to clopidogrel; Increased prevalence of CYP2C19×2 allele carrier status ⁱ	African Americans > Caucasians	Prothrombotic
High maximum platelet-fibrin clot strength ^j	African Americans > Caucasians	Prothrombotic
Differential regulation of Gq pathway after PAR-4 stimulation ^{k,l}	Blacks > Whites	Prothrombotic
CRP elevation ^{m,n}	African Americans > Hispanic > Caucasians > Asians	Proinflammatory

VWF= von Willebrand Factor; APC = Activated Protein C; CRP=C-reactive protein.

racial groups. The preliminary results confirming the hypothesis were recently reported by Zakeri et al.[6].

Currently, D-dimer is the most widely reported biomarker associated with COVID-19 severity and outcomes, with an escalation of antithrombotic therapy proposed in patients with very high levels [7,8]. However, there are several limitations of this biomarker to monitor thrombogenicity during COVID-19. Despite evidence of elevated D-dimer in patients with severe COVID-19, VTE was not evident in the majority. D-dimer, an acute phase reactant with low specificity in the critically ill with conditions associated with fibrin formation, is generated during fibrinolysis and reflects later stage clot formation and hemostatic processes. There is also considerable variation in D-dimer measurements and the reported units that has made pooling of the studies for interpretation unreliable. About 2 - 3% of plasma fibrinogen is physiologically converted to crosslinked fibrin and then degraded to D-dimer [9]. Thus, elevated levels of fibrinogen in COVID-19 patients, especially among AAs, likely contribute to higher D-dimer values without necessarily an associated increase in fibrinolytic activity. Hence, even if the fibrinolytic system is impaired, D-dimer values may be high. Finally, D-dimer does not provide quantitative information on platelet function, thrombin generation, and the kinetics of clot formation.

Some of these limitations can be addressed by global hemostasis assays such as thromboelastography or rotational thromboelastometry. Whereas high D-dimer in COVID-19 may be associated with a prothrombotic state, a hypofibrinolytic state, or both, viscoelastic measurements of clot provide greater insight into the dynamics of coagulation, platelet function and fibrinolysis. Viscoelastic measurements can quantitate the response to both anticoagulant and antiplatelet therapy [10]. Thromboelastography is a whole blood ex vivo assay that provides viscoelastic measurements of the evolving clot from the time of initial platelet-fibrin clot formation to clot

strengthening to clot lysis. It can be used to assess platelet function and coagulation, the response to antiplatelet and anticoagulant agents, and to quantify fibrinolysis. Among patients with COVID-19, determination of thrombogenicity phenotype and response to antithrombotic agents can help to personalize the antithrombotic regimen [10]. In an ongoing study, “The Evaluation of Hemostasis by Thromboelastography, Platelet Function Testing, and Biomarker Analysis in Hospitalized COVID-19 Patients (TARGET-COVID Study)” (NCT04493307) the influence of the early detection of hypercoagulability on COVID-19 outcomes is being investigated.

Racial disparities in the outcomes of COVID-19 are surely influenced by important social and economic factors. However, differences in mortality and thromboembolic event occurrences in COVID-19 may also be, in part, explained by important, but comparatively unrecognized, race-related disparities in intrinsic thrombogenicity. We hypothesize that a patient’s hemostatic blueprint determines clinical outcomes in COVID-19 and that early viscoelastic analysis of clot may facilitate future efforts to personalize antithrombotic therapy [10]. Such personalization holds the promise of mitigating the relationship of race to COVID-19 related outcomes.
